Measurements of Triple- and Double-Spin Parameters

In Elastic p-p Scattering at 6 GeV/c

ABSTRACT

Toward the goal of experimentally determining the pp elastic scattering amplitudes at 6 GeV/c, we have measured a number of triple- and double-spin correlation parameters over the |t| range between 0.2 and 1.0 (GeV/c)². These new data permit the first nucleon-nucleon amplitude determination in the multi-GeV energy range. Polarized beams from the Argonne ZGS and polarized targets were utilized. The polarization of the recoil proton was measured with a carbon polarimeter. A total of 14 different spin observables were measured (five spin transfer, four depolarization, and five triple-spin correlation parameters). These have been combined with earlier results, resulting in a data set of typically 30 measurements of 20 different spin observables for each of six |t| values between 0.2 and 1.0 (GeV/c)². A solution for the amplitudes has been found at each |t|, and comparisons are presented with several different models. The spin non-flip helicity amplitudes are found to be much larger than the spin-flip amplitudes.
I. Introduction

A series of experiments were performed several years ago at 6 GeV/c laboratory momentum to experimentally determine the p-p elastic scattering amplitudes in the region of four-momentum-transfer-squared $|t|$ up to about 1.0 (GeV/c)$^2$. Most of these earlier measurements were performed with polarized proton beams from the Argonne National Laboratory Zero Gradient Synchrotron (ZGS). They included complicated triple-spin experiments,\textsuperscript{1,2} with polarized beam and polarized target and a determination of the outgoing spin of one particle with a carbon polarimeter, as well as single- and double-spin measurements.\textsuperscript{3-14} The difficult triple-spin experiments measured more than one spin observable simultaneously, and they used polarized proton targets with spin aligned perpendicular to the scattering plane. The rapidly falling p-p differential cross section at 6 GeV/c made high precision measurements very difficult for $|t|$ above about 1.0 (GeV/c)$^2$.

This is a report on the last series of experiments carried out in the 6 GeV/c amplitude program. Polarized targets with spin aligned in the scattering plane were used. It has been shown that such measurements were needed to uniquely obtain the amplitudes in a model independent fashion.\textsuperscript{15} Results are presented for several triple-spin parameters, such as $H_{LSN} = (L,S;0,N)$ and $H_{NSS} = (N,S;0,S)$, and a number of double-spin parameters, such as $D_{SS} = (0,S;0,S)$ and $K_{LS} = (L,0;0,S)$. In some cases, mixtures of pure spin observables were obtained, such as $\bar{D}_{LS} = (a \cdot D_{LS} + b \cdot D_{SS})$, where $D_{LS} = (0,L;0,S)$ and $a$ and $b$ are $|t|$ dependent constants. Some results from these experiments have been published previously.\textsuperscript{12} Also, in some cases, the $|t|$ range was limited by the polarized target magnet aperture.

Combining the data from these measurements with previous results at 6 GeV/c\textsuperscript{1-14} gives up to 35 points and 21 different spin observables at some
values of $t$. Roughly half of these are presented in this paper. As a consequence of the large number of spin observables, the amplitudes are highly overconstrained. Therefore, many checks for systematic errors are discussed.

In Sec. II, we summarize the notation used for observables. Section III contains a description of the experimental apparatus; details of the methods used in data reduction are described in Sec. IV. We have used these new measurements to carry out a preliminary analysis of the p-p elastic-scattering amplitudes; the results are discussed briefly in Sec. V. The interpretations are given in Sec. VI, and the conclusions in Sec. VII.

II. Formalism

The general formalism has been presented in our previous paper$^1$ and is developed in the references cited therein. Spin directions for the beam, target, scattered and recoil protons are shown in Fig. 1.

Expressions of spin parameters (Beam, Target; Scattered, Recoil) in the laboratory system are as follows:

$$ P = (N, 0; 0, 0) = (0, N; 0, 0) = (0, 0; 0, N); \text{ polarization,} $$

$$ C_{ij} = (1, j; 0, 0); \text{ spin correlation parameters,} $$

$$ D_{ij} = (0, i; 0, j); \text{ depolarization parameters,} $$

$$ K_{ij} = (1, 0; 0, j); \text{ polarization transfer parameters,} $$

$$ H_{ijk} = (1, j; 0, k); \text{ triple-spin parameters,} $$

where $i, j, k$ denote a direction of measured spin ($N, L$ or $S$).

The elastic-scattering amplitudes may be defined in many different ways; we have chosen two which are widely used. The t-channel exchange amplitudes are defined so that each amplitude has definite quantum numbers at asymptotic energy;$^{16,17}$ these are $N_0$, $N_1$, and $N_2$ for natural-parity exchange and $U_0$ and
$U_2$ for unnatural-parity exchange. The s-channel helicity amplitudes$^{18-21}$ may be expressed as follows:

\begin{align}
<++|++> &= \phi_1 \\
<--|++> &= \phi_2 \\
<--|+-> &= \phi_3 \\
<+-|+-> &= \phi_4 \\
<++|+-> &= \phi_5.
\end{align}

(1)

The amplitudes $\phi_1$ and $\phi_3$ are net helicity non-flip, $\phi_2$ and $\phi_4$ are helicity double-flip, and $\phi_5$ is helicity single flip.

The t-channel exchange amplitudes are then:

\begin{align}
N_0 &= \frac{1}{2} (\phi_1 + \phi_3) \\
N_1 &= \phi_5 \\
N_2 &= \frac{1}{2} (\phi_4 - \phi_2) \\
U_0 &= \frac{1}{2} (\phi_1 - \phi_3) \\
U_2 &= \frac{1}{2} (\phi_2 + \phi_4).
\end{align}

(2)

The experimental observables expressed in terms of both sets of amplitudes are summarized in Tables 1a (Refs. 16, 21) and 1b (Ref. 22).

**III. Experimental Procedures**

The measurements were carried out with the same experimental apparatus using two different directions of the beam spin. Together with an $S$-type polarized target, an $N$-polarized beam was used for measurement of $H_{\text{NSS}}$ and an $L$-polarized beam for $H_{\text{LSN}}$. The two beam polarizations were alternated during the same running period so that most systematics are similar for the two
measurements. An approximately L-type polarized target was used for the measurement of $\tilde{D}_{LS}$ and other parameters. In this case, L-type and S-type beam polarizations were employed. Figure 2 shows one of the experimental setups, consisting of a beam line with a set of spin precessors (not shown), an S-type polarized target, a forward detecting system, and a recoil polarimeter. The other experimental setup is shown in Ref. 12.

A) Polarized Proton Beam

Polarized protons entered the beam transport system with spin along the vertical axis. For the $H_{LSN}$ measurement it was necessary that the spin direction be along the beam axis at the center of the polarized proton target (PPT). The magnetic field of the PPT magnet was perpendicular to the N-L plane; this caused significant ($\sim 20^\circ$) precession of the polarized beam. Consequently, the spin direction at the entrance of the PPT was oriented so that this additional rotation produced the spin direction required at the center of the target. Analogous situations existed for the $H_{NSS}$ and L-type target measurements. The proper beam spins were obtained with a versatile beam channel which used both solenoid and dipole magnets; the details have been given elsewhere.\textsuperscript{23}

For convenience, we define the polarization of the beam as follows:

$$\hat{P}_{\text{Beam}} = P_B (\alpha_N \cdot \hat{N} + \alpha_L \cdot \hat{L} + \alpha_S \cdot \hat{S})$$ \hspace{1cm} (3)

where $P_B$ is the magnitude of the polarization and the $\alpha_i$ are direction-cosines of the positive spin vector to unit vectors $\hat{N}$, $\hat{L}$ and $\hat{S}$ as shown in Fig. 1. The values $\alpha_N$ and $\alpha_S$ before the PPT and at the center of the PPT were calculated using the known beam transport parameters and the measured field of the PPT; they are summarized in Table 2. The additional deflection of the inci-
dent beam in the magnetic field of the PPT was also taken into account in the
experimental setup.

The polarity of the beam spin was reversed each spill (every few
seconds) to reduce systematic errors. The beam polarization was continuously
monitored with a polarimeter whose signals were analyzed by a computer in the
ZGS main control room. The intensity was typically $10^6$ protons/spill with
average polarization of 0.73.

B) Polarized Proton Target

The polarized proton target consisted of a target cell, a cryostat
and a magnet. The target cell had dimensions of 1.9 cm (W) × 2.0 cm (H) × 6.5
cm (L) and was filled with 2-mm-diameter beads of ethylene glycol (HOCH$_2$CH$_2$OH)
doped with $K_2Cr_2O_7$. It was cooled by a horizontal $^3$He refrigerator operating
near 0.4K.

The free protons were dynamically polarized by microwave excitation
in the 2.5 T field of the PPT magnet; this consisted of superconducting coils
in a Helmholtz-type configuration. The magnet apertures were cones of 48°
along the field axis; recoil protons emerged through one of these. There were
equatorial apertures of 21° for the passage of the beam and scattered protons.
For the L-target measurements, the beam and scattered protons passed through
one of the 48° cones and the recoil protons through the equatorial aperture.
In this case there was a restriction to the angular coverage at large $|t|$,
caused by the limited recoil aperture.

For the discussion of Section IV it is convenient to express the
target polarization as:

$$\hat{P}_{\text{Target}} = P_T (\beta_N \hat{N} + \beta_L \hat{L} + \beta_S \hat{S}),$$

where the definition of $P_T$ and the $\beta_i$ are analogous to those for the beam.
For the $H_{NS}$ and $H_{LS}$ measurements the target was oriented so that $\beta_s$ was equal to 1.0, while $\beta_n$ and $\beta_L$ were equal to zero (see Table 3). The magnetic field was oriented at $18^\circ$ to the beam for the $\bar{D}_{LS}$ measurements in order to be able to detect both the forward and recoil protons. The target polarization was monitored by an NMR system with a pick-up coil wound around the target cell. The NMR signals were read in and analyzed continuously by a PDP-11/20 computer. The polarity of the PPT was reversed at approximately two-hour intervals. The average polarization during the experiments was about 0.80.

C) Trigger Counters and Chambers

The experimental arrangement for the $H_{LS}$ and $H_{NSS}$ measurements is shown in Fig. 2a. The beam was defined by scintillation counters $S_0$ (placed far upstream of the PPT), $S_1$, and $S_2$. Beam halo was rejected by $BA_1$; particles not going through the PPT were rejected by $BA_2$. Scattered and recoil particles were identified by hodoscopes $F_1$ through $F_8$, and $R_1$ through $R_6$, respectively. Unscattered beam particles were vetoed. There were three pairs of multiwire proportional chambers (MWPC's) with $X$- and $Y$-planes both upstream of the PPT and in the forward arm for tracking beam and scattered particles.

The recoil particle was detected by a recoil polarimeter which consisted of four pairs of MWPC's and a carbon plate of thickness 5.08 cm that served as scatterer. Each pair of chambers had both $X$- and $Y$-planes with wire spacing of 2 mm. The two pairs of chambers before the carbon had an effective area of $51.2 \times 25.6 \text{ cm}^2$ and the two pairs behind had an effective area of $51.2 \times 51.2 \text{ cm}^2$. The polarimeter is shown schematically in Fig. 2b. The polarimeter was oriented so that its normal made an angle of $67.06^\circ$ and $71.25^\circ$ (for S- and L-targets, respectively) with respect to the beam axis.
The alignment of the polarimeter chambers was checked and calibrated using straight-through data with no PPT magnetic field and no carbon scatterer.

D) Trigger and Data Acquisition

Events were triggered by \((S_0 \cdot S_1 \cdot S_2 \cdot R_i \cdot F_i \cdot \overline{BA}_i \cdot \text{PEF})\), where PEF was the logic signal from a hard-wired "FAST EVENT FILTER". Output from the polarimeter chambers was supplied to this circuit which calculated the difference between the slope of tracks before and after the carbon scatterer. If the difference was larger than the preset value, the FEF would output an "OK" signal. Most unscattered events were rejected with this circuit, saving both tapes and computer time which would otherwise be used for analysis. The accepted data were read onto tape through CAMAC using an EMI 6050 computer.

IV. Data Analysis

A) Data Reduction

The data (a total of 38 M events) were analyzed in three stages:
a) filter, b) analysis, and c) polarimeter analysis. In the first stage, "filter", only those events having enough chamber information for track reconstruction were transmitted to the next stage; the transmission efficiency was about 50%.

In the second stage, "analysis", kinematical values were calculated for the first scattering, i.e., scattering at the PPT. In doing this it was necessary that corrections be made for the effects of the PPT magnetic field. The corrections were evaluated by generating large numbers of events with random scattering angle \((\theta, \phi)\) and interaction point within the PPT. For each event the energy losses in the PPT were calculated and the particles tracked through the magnetic field to the chamber planes. The simulated events were
fitted to obtain a correlation matrix among the coordinates of the interaction point, the scattering angles (\(\theta, \phi\)), and wire numbers in the chambers.

Cuts were made to the data for those events with interaction points outside the target, or too large distance between forward and recoil tracks, etc. However, no cut was made here for either the angle-angle correlation or coplanarity. The distribution of the interaction points at the target is shown in Fig. 3a. The distribution in coplanarity angle is shown in Fig. 3b; the coplanar peak is clearly resolved above the non-coplanar background. Approximately 70% of the events survived for stage three analysis.

The final stage of analysis involved the second-scattering at the recoil polarimeter. The MWPC's provided two sets of hit points both before and after the carbon scatterer so that the corresponding angles \(\theta_c\) and \(\phi_c\) could be calculated. The definition of these angles is illustrated in Fig. 4. The new Z-axis (Z') at the second scattering is along the direction of the recoil proton incident on the carbon plate. The corresponding Y-axis (Y') lies in the Y-Z' plane; the new X-axis (X') is given by Y'\times Z'. The scattering angles \(\theta_c\) and \(\phi_c\) in the carbon plate are measured with respect to the primed axes. Those events which did not have full acceptance in the last chamber, or events with too large distance between tracks before and after the carbon plate, were rejected. The scattering angle \(\theta_c\) was limited to the region 6° to 16° in order to be able to compare to the analyzing power of the polarimeter, \(A_{pC}\), as measured in our previous experiment.\(^1\) Even with the fast event filter, only about 5% of the events survived these cuts to be identified as good events. The typical histograms of the scattered-recoil correlation for both coplanar and noncoplanar events from the first scattering are shown in Fig. 5. The arrows in the histogram are the positions of the cuts. To estimate contributions from inelastic and quasi-free scattering from the carbon in the PPT the
noncoplanar events were normalized to the number of coplanar events outside
the cut-lines. Then at the recoil polarimeter the azimuthal distribution of
the normalized noncoplanar events was subtracted from that of the coplanar
events.

The superconducting magnet of the PPT, shown in Fig. 2, had a strength of
2.5T in the target region. It was designed with no return yoke to provide
maximum acceptance in the L- and S- configurations; the consequence, however,
is a large fringe field outside the magnet. The magnetic field remained
strong (0.6 to 0.2T) in the region of the polarimeter whose center was about
70 cm from the PPT. Since the recoil protons were of low momentum (0.4 to 1.2
GeV/c) it was important to correct for precession of their spins in the fringe
field.

In the analysis of the double-scattering events it is necessary to know
the orientation of the spin of the recoil proton immediately before the second
scattering in the polarimeter. For the azimuthal asymmetry the relevant part
is the projection $\gamma$ and the azimuthal angle $\phi_0$ in the $X'-Y'$ plane in Fig. 4.
We have calculated these values as a function of $|t|$ for recoils initially
(i.e., at the PPT) polarized along the L, N, and S directions. The results
are shown in Fig. 6a for the S-target measurements and Fig. 6b for the L-
target measurements; angles and energy losses were calculated in the
approximation that all interactions occurred in the center of the PPT.

After scattering by the carbon in the polarimeter the number of events in
the i-th azimuthal bin can be written as

$$N^{+\pm}(\phi_i) = n(\phi_i) I_0 [1 + a_0^{+\pm} - a_N^{+\pm} \sin(\phi_i - \phi_N)$$

$$- a_L^{+\pm} \sin(\phi_i - \phi_L) - a_S^{+\pm} \sin(\phi_i - \phi_S)] , \quad (5)$$
where the superscripts indicate directions of beam and target polarizations, and the coefficients $a_j$ may be expressed in terms of $P_B$, $P_T$, and the spin parameters. The distortion function, $\eta(\phi_1)$, takes into account the effect of the magnetic field on recoil protons, binning of events in the chamber, etc. The subscripts $N$, $L$, and $S$ denote the components of recoil spin at the PPT. The detailed expressions for $a_j$ and the experimental determination of the distortion function, $\eta(\phi_1)$, are given in the Appendix.

The data were taken for four combinations of beam and target polarizations. The azimuthal distributions were obtained for each $t$-bin used in the first scattering. The angular range of 360° was divided into 24 bins, -7.5° to 7.5°, 7.5° to 22.5°, etc. The raw azimuthal distributions were next corrected for beam and target polarizations, and the distortion function. The distributions were then normalized and constant terms subtracted; details are again described in the Appendix. The resulting distributions can now be expressed in terms of physical parameters of interest. For example, with a pure N-beam and S-target ($a_N = 1.00$, $S_S = 1.00$) the distributions are:

$$
\eta^{(1)}(\phi) = A_{pd} \gamma_N P \sin (\phi - \phi_N) \\
\eta^{(2)}(\phi) = A_{pd} \gamma_N K_{NN} \sin (\phi - \phi_N) \\
\eta^{(3)}(\phi) = A_{pd} \left[ \gamma_L D_{SL} \sin (\phi - \phi_L) \\
+ \gamma_S D_{SS} \sin (\phi - \phi_S) \right] \\
\eta^{(4)}(\phi) = A_{pd} \left[ \gamma_L H_{NSL} \sin (\phi - \phi_L) + \gamma_S H_{NSS} \sin (\phi - \phi_S) \right],
$$

where the definition of $\eta^{(1)}(\phi)$ is given in Eq. (A-13) of the Appendix.

In principle there are additional terms due to imperfect alignment of the initial spin states; however, with the high degree of spin alignment achieved in the present experiment (see Tables 2 and 3), their contributions are usual-
ly negligible. It is now possible to fit the experimental azimuthal distributions, \( n^{(k)}(\phi) \), for each \( t \)-bin to an expression of the above form with given values of the \( \gamma \) and \( \phi \) parameters; further details appear in the Appendix (see also Table 4). Note that in Eq. (6), \( \phi_S \) and \( \phi_L \) differ by approximately 90\(^\circ\), so that pure \( D_{SS} \) and \( N_{NSS} \) can be derived.

The results obtained are shown in Fig. 7 and listed in Table 5.

**B) Discussion of Systematic Errors**

The distortion function \( \eta(\phi) \) was introduced to take into account the effects of the magnetic field on recoil protons. However, there are other effects which could influence the empirical evaluation of this function through \( X_0(\phi) \) as described in the Appendix. For example, some structure is introduced if the relative normalization of beam and target polarizations is not correct. The magnitude of such an effect depends upon some spin parameter such as \( K_{NN} \), etc.

To check for such effects two methods of normalization were tried. The first normalization used the number of protons in the beam and the second used the number of unpolarized background events from the carbon. The latter was used only for the \( L \)-beam because an \( N \)-beam can produce an asymmetry on an unpolarized target. No significant difference was observed. The difference between the results obtained with these two normalizations was about an order of magnitude smaller than the statistical error quoted in Table 5.

As another test of the stability of our results we varied the value of the analyzing power \( (P) \) for \( p\cdot p \) scattering in obtaining \( \eta(\phi) \) and spin parameters from the azimuthal distributions. Differences due to variations in \( P \) of 0.01 to 0.02 were comparable with those described above. An internal check on the consistency of our normalizations is provided by comparing the values
of $D_{SS}$ and $D_{SL}$ obtained with the L- and N-beams and of $\tilde{D}_{LS}$ and $\tilde{D}_{LL}$ with L- and S-beams. The values are listed in Table 5 and are consistent within errors.

A Monte Carlo simulation provided a final check of the effect of the magnetic field. The effects of multiple scattering in the PPT and deflection in the fringe field over the region of the polarimeter were introduced. The events generated were analyzed by the same program used for the experimental data. The azimuthal distributions of these simulated events were compared with the observed distributions; the result is shown in Fig. 8. The fair agreement provides support for the assumption that the structure in the $\phi_C$ distribution is largely due to the magnetic field. More refined treatment of multiple scattering, energy loss, etc., would presumably provide even better agreement.

The normalization constants for double- and triple-spin parameters are given by:

$$f_K = A_{PC} \cdot P_B \cdot \alpha \cdot \gamma, \quad \text{for } (*, 0; 0, *) ,$$

$$f_D = A_{PC} \cdot P_T \cdot \beta \cdot \gamma, \quad \text{for } (0, *; 0, *) ,$$

(7)

and

$$f_H = A_{PC} \cdot P_B \cdot P_T \cdot \alpha \cdot \beta \cdot \gamma, \quad \text{for } (*, *; 0, *) ,$$

where $A_{PC}$ is the analyzing power for the p-C scattering, taken from Ref. 24.

The normalization errors for absolute beam and target polarizations are estimated to be about $\pm 5\%$. The direction of beam and target spins were known to accuracies of $\pm 3.5^\circ$ and $\pm 0.5^\circ$ respectively. These errors are listed in Tables 2 and 3; they are negligible for the coefficients of the large components in Table 4 (also see Appendix). The sources of the error in $\gamma$ and $\phi_C$ result from accuracy of knowledge of the magnetic field and approximation
in the calculation itself. A summary of the systematic errors due to $\alpha$, $\beta$ and $\gamma$ is presented in Table 6a. The values of $A_{pC}$ and their estimated systematic uncertainties are given in Table 6b.

The errors in normalization may be estimated by combining those errors for the large component in quadrature. We obtain:

$$\frac{\Delta f_K}{f_K} \sim \frac{\Delta f_D}{f_D} \sim 0.05,$$

$$\frac{\Delta f_H}{f_H} \sim 0.07.$$

(8)

No error has been included for the analyzing power of the polarimeter.

There is no observable in the present experiment which provides a useful internal calibration of the polarimeter. In principle, the polarization $(0,0;0,N)$ could provide such a calibration; however, the small azimuthal asymmetry in the second scattering is completely masked by other effects. As an approximation we have used the values of $A_{pC}$ polarization measured in previous experiments.\textsuperscript{24} Further discussion on $A_{pC}$ is given in Sec. IV D.

C) **Consistency Checks with Existing Data**

There are a number of internal consistency checks which can be applied to the present data to search for possible systematic errors. The first three deal with data whose carbon analyzing powers $A_{pC}$ are all related. Then, there are checks for systematic errors for observables which should vanish. Additional tests which permit comparisons of $A_{pC}$ to other experiments are given in the next subsection.

Time reversal invariance leads to some simple relations in the c.m. frame. Converting the spin directions to the laboratory system leads to the equation\textsuperscript{21}
\[(D_{SS} - D_{LL}) = \cot \theta_R \cdot (D_{LS} + D_{SL}),\]  

(9)

where $\theta_R$ is the laboratory recoil angle. This relation can also be derived from the formulae in Table 1. Note that the carbon analyzing power $A_{pC}$ cancels in this equation, so this is a test for other types of systematic errors. From Table 5, the S-target measurements provide pure values of $D_{SS}$ and $D_{SL}$. The L-target data give mixtures of $D_{LS}$ and $D_{SS}$ ($D_{LS}$) and of $D_{LL}$, $D_{SL}$, and $D_{NN}$ ($D_{LL}$). It was assumed that $D_{NN} = 0.95$ over the angular range of this experiment; this is the same assumption made in Ref. 1 to obtain $A_{pC}$. Derived values of the pure $D_{ij}$ spin parameters and of the two sides of Eq. (9) are given in Table 7. The results of this test are also plotted as a function of $-t$ in Fig. 9a. It can be seen that the data are consistent with Eq. (9).

Arguments similar to those above lead to the equation

\[(K_{SS} - K_{LL}) = \cot \theta_R \cdot (K_{LS} + K_{SL}).\]  

(10)

From Table 5, the S-target measurements provide pure values of $K_{NN}$ and $K_{LS}$, and a mixture of $K_{NN}$ and $K_{LL}$. The L-target data provide two mixtures of $K_{SS}$ and $K_{LS}$ and two mixtures of $K_{NN}$, $K_{SL}$ and $K_{LL}$. Finally, Ref. 1 provides another mixture of $K_{SS}$, $K_{LS}$, $K_{SL}$, and $K_{LL}$. From this information, pure $K_{ij}$ spin parameters were derived as well as the quantities $(K_{SS} - K_{LL})$ and $\cot \theta_R$ $(K_{LS} + K_{SL})$. The numerical values are given in Table 8, and the last two quantities are also plotted in Fig. 9b. Again, the results are consistent with Eq. (10). Other checks of this type, for example

\[
(H_{LNL} - H_{SNS}) = \tan \theta_R \cdot (H_{LNS} + H_{SNL}),
\]

(11)

\[
(H_{NLL} - H_{NSS}) = \tan \theta_R \cdot (H_{NLS} + H_{NSL}),
\]
could not be made for lack of sufficient data.

Another check of the $K_{NN}$ results can be made by comparison to previous measurements of Fernow et al. $^2$ Near $-t = 0.5$ (GeV/c)$^2$, the earlier data gave $K_{NN} = 0.14 \pm 0.08$, whereas Table 5 gives $K_{NN} = 0.114 \pm 0.037$; see also Fig. 7. This check does not provide a strong test of the value of $A_{PC}$ because the same polarimeter and carbon analyzing power was used to obtain $K_{NN}$ and $D_{NN}$ in Ref. 2. In turn, these values of $D_{NN}$ were used to obtain $A_{PC}$ for the polarimeter in Ref. 1, which are similar to the $A_{PC}$ used in this paper. In summary, there are no indications of sizeable systematic errors in the data on the basis of the last three checks.

Another test for systematic errors involves a comparison between $D_{SS}$ data of the Saclay group $^5$ and the present results; both are shown in Fig. 7. Although the earlier measurements have sizeable statistical uncertainty, there is some indication that the present data may be too small in the region $-t = 0.3$ to $0.4$ (GeV/c)$^2$. Otherwise there is satisfactory agreement.

Finally, parity conservation requires that only spin observables with an even number of L and S subscripts may be different from zero. In a number of measurements performed during these experiments, spin parameters which should nearly vanish were obtained. These include $\tilde{H}_{LNS}$ with an L-beam and L-target, and $\tilde{H}_{SNS}$ with an S-beam and L-target, for which the coefficients in Table 4 are quite small. These results are plotted in Fig. 10 and they are all consistent with zero within statistics, as expected. This test demonstrates that sizeable instrumental asymmetries are not present in the data.

D) \textbf{The Carbon Analyzing Power}

It was not possible to obtain an internal calibration of the carbon analyzing power $A_{PC}$ from these data. As a consequence, values from Ref. 24
were used. Some tests are possible to verify that $A_{PC}$ was the same for the $S$-target and L-target data reported in this paper. Other tests allow cross checks with earlier data. Finally, the value of $A_{PC}$ can be compared to results of our previous measurements.\footnote{1}

A test of the consistency of $A_{PC}$ between the S- and L-target data can be performed using the $D_{SS}$, $D_{SL}$, $\tilde{D}_{LS}$ and $\tilde{D}_{LL}$ results. In order to satisfy Eq. (9), the ratio of analyzing powers for L- to S-target data must be

$$A_{PC}(L)/A_{PC}(S) = 0.82 \pm 0.40 \ (t = -0.27)$$

$$= 0.63 \pm 0.18 \ (t = -0.38)$$

Both of these values are consistent with the value 1.00 assumed in this paper.

A different type of test is permitted if it is assumed that the $N_0$ amplitude is dominant and purely positive imaginary. Then the parameters $C_{NN}$ and $K_{NN}$ can be expressed as follows:

$$C_{NN} = 2 \operatorname{Re}(-N_0N_2)/\sigma = -2\frac{\text{Im}N_2}{|N_0|},$$

$$K_{NN} = -2 \operatorname{Re}(N_0N_2^*)/\sigma = -2\frac{\text{Im}N_2^2}{|N_0|^2}.$$  \hspace{1cm} (13)

Thus, $C_{NN}$ should be approximately the same as $K_{NN}$. Another way to show this is to use the expressions in Table 1c:

$$1 - D_{NN} = 2 \{ |U_0|^2 + |U_2|^2 \}/\sigma,$$

$$C_{NN} - K_{NN} = 4 \operatorname{Re} U_0U_2^*/\sigma.$$

So,

$$1 - D_{NN} > |C_{NN} - K_{NN}|.$$  \hspace{1cm} (14)
At $-t \sim 0.27$ and $0.38 \ (\text{GeV}/c)^2$, the data of Miller et al.\textsuperscript{10} give $C_{NN} = 0.066 \pm 0.011$ and $0.069 \pm 0.014$, and from Table 5, $K_{NN} = 0.134 \pm 0.045$ and $0.126 \pm 0.025$ respectively. The relation in Eq. (14) is also shown in Fig. 11 using data from Refs. 2, 9, 10, 14. Note that $l$ and $C_{NN}$ do not depend on $A_pC$, but that $K_{NN}$ and $D_{NN}$ are inversely proportional to the carbon analyzing power.

Defining the rotated spin parameters

\[
(a, \beta; 0, R) = (a, \beta; 0, S) \cos \theta_R + (a, \beta; 0, L) \sin \theta_R
\]

(15)

\[
(a, \beta; 0, R) = (a, \beta; 0, L) \cos \theta_R - (a, \beta; 0, S) \sin \theta_R,
\]

then additional inequalities similar to Eq. (14) can be derived. For example,

\[
1 + D_{NN} > |C_{NN} + K_{NN}|
\]
\[
1 + D_{SR} > |C_{SS} + K_{SR}|
\]
\[
1 + D_{SR} > |H_{SNR} - H_{SLN}|
\]
\[
1 - D_{SR} > |C_{SS} - K_{SR}|
\]
\[
1 - D_{SR} > |H_{SNR} + H_{SLN}|
\]
\[
1 + D_{LT} > |C_{LL} + K_{LT}|
\]
\[
1 + D_{LT} > |H_{LNR} - H_{LSN}|
\]
\[
1 - D_{LT} > |C_{LL} - K_{LT}|
\]
\[
1 - D_{LT} > |H_{LNR} + H_{LSN}|
\]

(16)

In general, there are insufficient $H_{ijk}$ data to test these expressions. Since $D_{SR}$ and $D_{LT}$ are both negative, the most stringent tests involve $(1 + D_{SR})$ and $(1 + D_{LT})$ in Eqs. (16) above. The values of $D_{SR}$, $D_{LT}$, $K_{LR}$ etc. are given in Tables 7 and 8 and data for the inequalities are shown in Fig. 11 using data.
from Refs. 11, 12. (Note that the relations, $D_{LR} = -D_{SR}$, $K_{LR} = -K_{SR}$, $H_{LR} = H_{SR}$, $H_{RL} = H_{NSR}$ lead to Eqs. (9-11) respectively.)

A number of other inequalities can also be derived from the expressions in Table I. For example,

$$
1 + C_{NN} > |C_{SS} - C_{LL}|
$$

$$
1 + C_{NN} > |H_{LSN} + H_{SLN}|
$$

$$
1 - C_{NN} > |C_{SS} + C_{LL}|
$$

$$
1 - C_{NN} > |H_{LSN} - H_{SLN}|
$$

$$
1 + K_{NN} > |K_{SR} + K_{LR}|
$$

$$
1 + K_{NN} > |H_{SNR} - H_{LNR}|
$$

$$
1 - K_{NN} > |K_{SR} - K_{LR}|
$$

$$
1 - K_{NN} > |H_{SNR} + H_{LNR}|
$$

$$
1 + D_{NN} > |D_{SR} + D_{LR}|
$$

$$
1 + D_{NN} > |H_{NSR} - H_{NLR}|
$$

$$
1 - D_{NN} > |D_{SR} - D_{LR}|
$$

$$
1 - D_{NN} > |H_{NSR} + H_{NLR}|
$$

Again, there are insufficient $H_{ijk}$ data to perform these tests. The fact that $C_{NN}$ and $K_{NN}$ are small means that the corresponding expressions above are not very stringent. Therefore, the only strong test is provided by the $(1 - D_{NN})$ equation. This is also shown in Fig. 11 using data from Ref. 2, 9 and 14.

The conclusion from the tests shown in Fig. 11 is that there is little evidence for problems with the carbon analyzing power $A_{PC}$ except for the last inequality at $t = -0.51$. For this point, the discrepancy is 2-3 standard deviations, which may not be statistically significant. In addition to Fig.
11, it should be noted that $D_{SL}$ is significantly below -1.0 at the largest angles. On the other hand, the systematic error on $D_{SL}$ from Table 6a is $\pm 33\%$, since $(0.24 \pm 0.08) D_{SL}$ is measured (see Table 4).

Figure 12 shows a plot of $A_pC$ from a variety of other polarimeters, as well as from this polarimeter measured in Ref. 1. There is good agreement within the rather sizeable errors of Ref. 1. On the other hand, the data summarized in Ref. 24 are not weighted by the differential cross section or acceptance, and they are integrated over scattering angles in the carbon, $\theta_C$, from 6° to 20°, whereas the range was $\theta_C \sim 6^\circ$ to 16° for the polarimeter in this paper.

There are a number of reasons that the recoil particle energies could be different in Ref. 1 and in these experiments for a given scattering angle in the polarized target. Small alignment errors of the chamber positions could have caused slightly different $t$-ranges in the two cases. There also could have been differences in the location of the beam spot center within the target flask, since the beam and target could only be aligned within $\pm 1-2$ mm. This could have affected the recoil particle energy losses. Finally, the carbon analyzer thickness in Ref. 1 was 1.90 cm at small $|t|$ and 7.62 cm at large $|t|$, whereas it was 5.08 cm at all $t$ in these experiments.

As a consequence of these differences, the values of $A_pC$ used in this experiment have been estimated from Fig. 12 and from the calculated energy losses in the polarized target, carbon, etc. The results are given in Table 6. Compared to Ref. 1, the values are unchanged at $-t = 0.51$ and 0.66 $(\text{GeV/c})^2$, and somewhat lower at $-t = 0.38$, 0.83, and 1.00 $(\text{GeV/c})^2$. A significant difference occurs at $-t = 0.27 (\text{GeV/c})^2$ from the thicker carbon used in these experiments. Generous uncertainties on $A_pC$ have been assigned to allow
for the differences noted above, as well as the effects of the differential cross section and acceptance.

V. **Amplitude Analysis**

An amplitude analysis was performed using the data in Table 5 together with existing results.\(^1\)-\(^{14,25}\) The amplitudes are normalized so that \(\sigma \equiv d\sigma/d\Omega = 1\). The procedure to obtain the amplitudes is described in Ref. 15; it is similar to the method of Gahramany, Goldstein and Moravcsik.\(^{26}\) In the fits, statistical and systematic errors were combined for all data with the exception of the results in this paper. Even though extensive random searches were performed at all angles, it is not certain that the amplitude solutions found are either unique or correspond to the minimum chi-squared per degree of freedom (\(\chi^2/d.f.\)). This is especially true at larger \(|t|\), where there are fewer data and the statistical errors are larger.

The results of the amplitude analysis indicate that the amplitude \(N_0\), which is taken to be purely positive imaginary, is dominant. Under these circumstances, the amplitudes can be readily evaluated because the observables can be expressed in the simple forms shown in Table 9a; the inverse expressions (amplitudes in terms of observables) are shown in Table 9b. The derived exchange amplitudes are found in Table 10.

The amplitudes in Table 10 are shown with two errors. The first is a "statistical error" corresponding to an increase in \(\chi^2\) by 1.0 from the minimum value. The corresponding minimum \(\chi^2/d.f.\) is also shown in Table 10, and its value is typically 1.4. The second error corresponds to the inclusion of the systematic uncertainties shown in Table 6. In some cases, this second error is substantially larger than the first error.
If it proves necessary to modify the values in Table 5 for a different value of carbon analyzing power, they can be scaled as \( A_p C^{-1} \). In particular, it can be shown that the distortion function \( \eta(\phi) \) defined in the Appendix is very insensitive to \( A_p C \). For example, the error in the spin parameters in Table 5 caused by ignoring \( \eta(\phi) \) is far less than the statistical uncertainties for changes in \( A_p C \) by a factor of 2.

The results of the amplitude determination are shown in Fig. 13a for the exchange amplitudes and in Fig. 13b for the s-channel helicity amplitudes. Note that the magnitudes of \( N_0, \phi_1 \) and \( \phi_3 \) are scaled down a factor of 5 in Fig. 13.

**VI. Interpretation**

Although there have been extensive measurements, pp elastic scattering at high energies remains one of the least understood processes. Even with its large cross section at small angles and its symmetry properties, the complexities associated with five scattering amplitudes and the experimental difficulties of performing many different spin measurements to determine these amplitudes, have limited the detailed knowledge on this reaction.

For example, it was generally expected that \( N_0 \) is the dominant amplitude at small angles.\(^{27-30}\) However, in spite of all the experiments at 6 GeV/c prior to these measurements,\(^{1-14}\) the dominance of the \( N_0 \) amplitude was not well established.\(^{31-33}\) With the new data in this paper, \( N_0 \) dominance at small angles is now experimentally verified, as shown in Fig. 13.

Several approaches have been used in the past to study the spin structure of the amplitudes from the 6 GeV/c data in Refs. 1-14. The most standard approach has been the use of the Regge-pole-exchange model. Berger, Irving and Sorensen\(^{27}\) have used such a model with parameters determined from other
reactions, as well as pp elastic scattering at various energies, to predict the pp amplitudes at 6 and 12 GeV/c. Their work is generally considered the standard model in this field. Kroll, Leader and von Schlippe have used dispersion-theoretic calculations, information from other reactions, and some "physically reasonable assumptions" about some of the helicity flip amplitudes to compute the pp amplitudes at 6 GeV/c. Wakaizumi and Sawamoto have investigated the pp interaction at 6 and 12 GeV/c at all angles using the impact parameter representation and the eikonal model. Fits to previous data allowed conclusions on the magnitudes of the short-, medium- and long-range components of the spin dependent eikonals. Finally, semiphenomenological phase shift analyses have been performed at 6 GeV/c using data from Refs. 1-14 as well as total and differential cross sections.

In general, there is fair agreement between the amplitude analyses in Refs. 27-30 and the amplitudes given in Fig. 13. The absolute phase of $N_0$ is slightly different in these models. Since this phase cannot be determined with the present data, $N_0$ will be taken to be purely positive imaginary in the discussion below. At $|t| = 0.38 (\text{GeV/c})^2$, the largest disagreements between predictions and the observed amplitudes occur for $\text{Im}(N_1)$, where Berger et al. have positive values and Wakaizumi et al. have more negative values than Fig. 13; for $\text{Re}(N_2)$, where Kroll et al. have positive values while Fig. 13 shows slightly negative results; and for $\text{Im}(N_2)$, where Matsuda et al. predict positive values and Fig. 13 has negative values. There is rough agreement on the magnitude and phase for $U_0$ and $U_2$ between these models and the amplitudes in Fig. 13, however the magnitude of $N_0$ is observed to be somewhat smaller than the model predictions.

Moravcsik, Goldstein and coworkers have commented on pp elastic scattering at 6 GeV/c in many articles. Several papers deal with the problem
of how best to determine the amplitudes. An extensive amplitude analysis from \( -t = 0.05 \) to \( 1.0 \) (GeV/c)\(^2\) has also been performed.\(^{26,34} \) Four different solutions with approximately the same \( \chi^2/d.f. \) were found; set 3 seems closest to the results in Fig. 13. A comparison of these solutions to the Regge-pole-exchange model of Berger et al.\(^{27} \) is given in Ref. 33. Polarization tests of one-particle-exchange mechanisms have been applied to the 6 GeV/c amplitudes and have been shown to be satisfied, whereas they fail at lower energies.\(^{35} \) Finally, these authors also interpret the results for the 6 GeV/c amplitudes in the framework of QCD.\(^{36} \) In particular, the data show that the spin non-flip helicity amplitudes \( \phi_1 \) and \( \phi_3 \) are much larger than the spin-flip amplitudes. This indicates that helicity conserving exchange terms are dominant, as would be the case if exchanged gluons couple to current quarks in the nucleons.

The amplitude picture seems easier to understand in terms of the s channel helicity amplitudes, where little variation is observed in \( \phi_1, \phi_3 \) and \( \phi_5 \) over most of the t-range of this experiment. As noted above, the dominant amplitudes are \( \phi_1 \approx \phi_3 \). In addition, the \( \phi_2 \) amplitude remains almost (relatively) real up to |\( t \) = 1.0 (GeV/c)\(^2\), though there is a change in its magnitude and direction. There is, however, a large variation in both the magnitude and direction of \( \phi_4 \). As has been noted by Kroll et al.,\(^{28} \) "surprisingly, the most interesting structure is in \( \phi_2 \) and \( \phi_4 \) themselves rather than in the combinations" \( N_2 \) and \( U_2 \). It is hoped that these measurements will stimulate further work to understand this structure in the helicity double-flip amplitudes.
VII. Conclusions

New experimental results on double- and triple-scattering spin parameters in pp elastic scattering at 6 GeV/c are presented. These allow the first nucleon-nucleon amplitude determination in the multi-GeV range, where a model independent analysis is the only reliable method to obtain the amplitudes at present. These results are consistent with dominance of the spin non-flip helicity amplitudes ($\phi_1$, $\phi_3$, $N_0$) at all $|t|$ from 0.27 to 1.0 GeV$^2$/c$^2$. A search for amplitudes that correspond to all 6 GeV/c spin data yielded the results shown in Fig. 13. Even though many searches were performed, it is not certain that the amplitudes in Fig. 13 are either unique or correspond to the minimum $\chi^2$/d.f. This is especially true at $-t = 0.83$ and 1.00 (GeV/c)$^2$, where there are fewer data and larger statistical errors.

Many tests for systematic errors were performed, as well as a number of consistency checks. In general, the data are internally consistent, although there are a few cases where 2-3 standard deviation discrepancies occur. Various tests indicate agreement with previous data, except that the new DSS values may be slightly smaller in magnitude than the data in Ref. 5. Various differences from Ref. 1 led to the adoption of carbon analyzing power ($A_{PC}$) values from measurements with other polarimeters. Particularly uncertain is $A_{PC}$ at $t = -0.27$ (GeV/c)$^2$. We encourage a remeasurement of some spin parameters at this angle to reduce the uncertainty on $A_{PC}$ and consequently on the amplitudes.
VIII. Acknowledgements

We wish to acknowledge the assistance of Drs. C. Chang-Fang and P. Rynes during the data analysis, R. Daly, O. Fletcher, F. Paulis, B. Millar, W. Haberichter, T. Kasprzyk, and A. Rask during the data taking periods, and R. Laverick for typing the manuscript. We also express appreciation to the ZGS operations staff. Finally, we wish to thank Drs. E. Berger, G. Thomas, C. Sorensen and other members of the ANL theory group and Drs. M. Moravcsik and G. Goldstein for many useful discussions on these data.

This work was supported in part by the U.S. Department of Energy.

### Table 3

#### Spin-Direction of the Target

The target spin components for Eq. 4 are given below for the two target configurations of this experiment.

**S-target**

| \( \beta_S \) | \( 1.00000 + 0 \)  
|              | \(- 4 \times 10^{-5} \)  
| \( \beta_L \) | \( 0.00 + 0.01 \)  
|              | \(- 0 \)  
| \( \beta_N \) | \( 0.00 + 0.01 \)  
|              | \(- 0 \)  

**L-target**

| \( \beta_S \) | \( 0.309 \pm 0.008 \)  
| \( \beta_L \) | \( 0.951 \pm 0.003 \)  
| \( \beta_N \) | \( 0.00 \pm 0.01 \)  
|              | \(- 0 \)

Table 5  
Measured Observables with S- and L-Targets

Numerical values for the pure spin parameters, such as $K_{LS}$, $D_{SL}$, $H_{NSS}$, have been corrected by the components in Table 4. No corrections have been applied for the mixed spin parameters, such as $K_{LL}$, $H_{LN}$ or $H_{SMS}$. The errors quoted are statistical only. Estimated systematic uncertainties are given in Table 6.

Table 6a

Estimated Systematic Uncertainties (excluding carbon analyzing power)

Fractional errors on the experimental measurements are estimated below. Contributions are from uncertainties in the beam, target and recoil spin projections, $\alpha$, $\beta$, $\gamma$, from Table 4 and from the beam and target polarization, $P_B P_T$. Note especially the large systematic uncertainties for the S-target parameters $\bar{K}_{LL}$, $D_{SL}$ and $\bar{H}_{NSL}$.

Table 6b

**Estimated Values of \( A_{pC} \) and Systematic Uncertainties**

The estimated values of the carbon analyzing power, \( A_{pC} \), were taken from Fig. 12 and Ref. 24. Previously measured values (Ref. 1) with a thinner carbon scatterer at small \( t \) are also included. The quoted uncertainties are estimated systematic errors for this experiment and statistical errors for the data from Ref. 1.

TABLE 10
Exchange Amplitudes Derived from the World's Data for pp Elastic Scattering at 6 GeV/c and Small -t

The amplitude $N_0$ is assumed to be positive imaginary. The uncertainties on the amplitudes correspond to an increase in $\chi^2$ by a value of 1.0 (statistical only) and to combined and systematic errors. The number of experimental data, the $\chi^2$ per degree of freedom, and the number of different spin observables used in the amplitude determination (excluding $d\sigma/dt$) are also tabulated.

APPENDIX

Recoil protons from elastic scatterings on the PPT were binned into intervals in $t$ (four-momentum-transfer-squared). The azimuthal distribution for recoil protons elastically scattered by the carbon in the polarimeter can then be written:

$$N^{++}(\phi_1) = \delta(\phi_1) I_0 \left[ 1 + a_0^{++} - a_0^{++} \sin(\phi_1 - \phi_N) ight]$$

$$- a_L^{++} \sin(\phi_1 - \phi_L) - a_S^{++} \sin(\phi_1 - \phi_S),$$

(A-1)

where superscripts $++$ indicate the polarities of the beam and the target polarizations. The coefficients $a_\lambda$ may be expressed in terms of observables according to:

$$a_0 = (a_{NB} + \beta_{NP} P) + P_{PB} \left[ a_{NN} C_{NN} + a_{LL} C_{LL} + a_{SS} C_{SS} ight]$$

$$+ (a_{LS} + a_{SL}) C_{LS},$$

$$a_N = a_{PCY} \left[ P + a_{NN} P_B K_{NN} + \beta_{NP} D_{NN} + P_{PB} \left( a_{NN} P + a_{LS} H_{LSN} + a_{LL} H_{LLN} ight) ight.$$ 

$$+ a_{LS} H_{SLN} + a_{SS} H_{SSN})$,}

$$a_L = a_{PCY} \left[ P + a_{NN} P_B K_{LL} + a_S K_{SL} \right] + P_T \left( \beta_L D_{LL} + \beta_S D_{SL} \right)$$

$$+ P_{PB} \left[ a_{NN} H_{NN} + a_{LS} H_{LSN} + a_{LL} H_{LLN} + a_{SS} H_{SSN} \right]$$,

$$a_S = a_{PCY} \left[ P + a_{NN} P_B K_{LS} + a_S K_{SL} \right] + P_T \left( \beta_L D_{LS} + \beta_S D_{SS} \right)$$

$$+ P_{PB} \left( a_{NN} H_{NN} + a_{LS} H_{LSN} + a_{LL} H_{LLN} + a_{SS} H_{SSN} \right),$$

(A-2)

where $A_{PC}$ is the analyzing power of the carbon polarimeter; the other parameters are defined in the text. Spin parameters such as $H_{SSN}$ disappear because of the symmetry properties of elastic p-p scattering.

Terms in Eq. (A-1) involving $P_B$, $P_T$ and $P_{PB}$ can be combined so that

$$N^{++}(\phi_1) = \delta(\phi_1) I_0 X_0(\phi_1) + P_B^{++} X_B(\phi_1) + P_T^{++} X_T(\phi_1) + (P_{PB})^{++} X_{BT}(\phi_1),$$

with

\[
X_O = 1 - A_{PC} \gamma_N \eta^p \sin(\phi_1 - \phi_N),
\]

\[
X_B = \alpha_N P - A_{PC} (\gamma_N N^N K_{NN} \sin(\phi_1 - \phi_N) + \gamma_L (\alpha_L K_{LL} + \alpha_S K_{SL}) \sin(\phi_1 - \phi_L) + \gamma_S (\alpha_L K_{LS} + \alpha_S K_{SS}) \sin(\phi_1 - \phi_S)),
\]

\[
X_T = \beta_N P - A_{PC} (\gamma_N N^N D_{NN} \sin(\phi_1 - \phi_N) + \gamma_L (\beta_L D_{LL} + \beta_S D_{SL}) \sin(\phi_1 - \phi_L) + \gamma_S (\beta_L D_{LS} + \beta_S D_{SS}) \sin(\phi_1 - \phi_S)),
\]

\[
X_{BT} = \alpha_{N^N} C_{NN} + \alpha_{N^L} C_{LL} + \alpha_{S^N} C_{SS} + (\alpha_{L^N} + \alpha_{S^N} C_{LS} - A_{PC} (\gamma_N (\alpha_{N^N} P + \alpha_{L^N} H_{LL} + \alpha_{S^N} H_{SL} + \alpha_{S^N} H_{SS}) + \gamma_L (\alpha_{N^L} H_{NN} + \alpha_{L^N} H_{LL} + \alpha_{S^N} H_{SL} + \alpha_{S^N} H_{SS}) \sin(\phi_1 - \phi_L) + \gamma_S (\alpha_{N^N} H_{NL} + \alpha_{S^N} H_{NL} + \alpha_{S^N} H_{NSL} + \alpha_{S^N} H_{NS}) \sin(\phi_1 - \phi_S))
\]

Equation (A-3) may be expressed in matrix form

\[
\begin{bmatrix}
N^{++} \\
N^{+} \\
N^{+-} \\
N^{-+} \\
N^{--}
\end{bmatrix} = n \cdot I_o \cdot \begin{bmatrix} X_O \\ X_B \\ X_T \\ X_{BT} \end{bmatrix}
\]

(A-5)

with

\[
M_{pol} = \begin{bmatrix}
1 & P_B^{++} & P_T^{++} & (P_B P_T)^{++} \\
1 & P_B^{+-} & P_T^{+-} & (P_B P_T)^{+-} \\
1 & P_B^{-+} & P_T^{-+} & (P_B P_T)^{-+} \\
1 & P_B^{--} & P_T^{--} & (P_B P_T)^{--}
\end{bmatrix}
\]

(A-6)
where explicit dependence on the angle $\phi_c$ has been suppressed. Inverting Eq. (A-6) we obtain

$$
\eta I_0 \cdot \begin{bmatrix}
X_0 \\
X_B \\
X_T \\
X_{BT}
\end{bmatrix} = X_{pol}^{-1} \cdot \begin{bmatrix}
N^{++} \\
N^{-+} \\
N^{+-} \\
N^{--}
\end{bmatrix},
$$

(A-7)

where the right-hand side of the equation depends only on the experimental data.

The first component of the vector $X$ in Eq. (A-5) is

$$
X_D^{Cal}(\phi_4) = 1 - A_p c N P \sin(\phi_4 - \phi_N),
$$

(A-8)

which can be independently calculated for each $\phi_4$-bin using existing polarization data and calculated values for the parameters $\gamma_N$ and $\phi_N$.

A new vector, $X_{exp}$, may also be defined using only the experimental data

$$
\eta I_0 \cdot \begin{bmatrix}
X_0^{exp} \\
X_B^{exp} \\
X_T^{exp} \\
X_{BT}^{exp}
\end{bmatrix} = X_{pol}^{-1} \cdot \begin{bmatrix}
N^{++} \\
N^{-+} \\
N^{+-} \\
N^{--}
\end{bmatrix}.
$$

(A-9)

The distortion function is then obtained directly:
\[ n(\phi_1) = X_0^{\exp}(\phi_1)/X_0^{\cal}(\phi_1) \]  \hspace{1cm} (A-10)

For the present analysis, \( n(\phi_1) \) was fitted by a polynomial function

\[ n(\phi) = \sum_{n=0}^{3} C_n \cos^n \phi + \sum_{n=1}^{3} S_n \sin^n \phi \]  \hspace{1cm} (A-11)

With this function, the corrected distribution becomes

\[ X_k(\phi_1) = \frac{X_k^{\exp}(\phi_1)}{n(\phi_1)} \; ; \; k = B, T \text{ and } BT \]  \hspace{1cm} (A-12)

Using available data for \( P, C_{NN}, C_{LL}, C_{SS} \), and \( C_{LS} \) we can generate another set of azimuthal distributions without constant terms:

\[ n^{(1)}(\phi_1) = 1 - X_0(\phi_1) \]
\[ n^{(2)}(\phi_1) = \alpha_{NP} - X_B(\phi_1) \] \hspace{1cm} (A-13)
\[ n^{(3)}(\phi_1) = \beta_{NP} - X_T(\phi_1) \]
\[ n^{(4)}(\phi_1) = \alpha_{NP} C_{NN} + \alpha_L^L C_{LL} + \alpha_S^S C_{SS} + (\alpha_L^S + \alpha_S^L) C_{LS} - X_{BT}(\phi_1) \]

These expressions can be expressed explicitly through the single-, double-, and triple-spin parameters as
\[ n^{(1)}(\phi) = A_p n y_N P \sin(\phi - \phi_N) \]

\[ n^{(2)}(\phi) = A_p \gamma_N^N K_{NN} \sin(\phi - \phi_N) + \gamma_L^L (\alpha_L^L K_{LL} + \alpha_S^L K_{SL}) \sin(\phi - \phi_L) + \gamma_S^S (\alpha_L^S K_{LS} + \alpha_S^S K_{SS}) \sin(\phi - \phi_S) \}

\[ n^{(3)}(\phi) = A_p \gamma_N^N D_{NN} \sin(\phi - \phi_N) + \gamma_L^L (\beta_L^L D_{LL} + \beta_S^L D_{SL}) \sin(\phi - \phi_L) + \gamma_S^S (\beta_L^S D_{LS} + \beta_S^S D_{SS}) \sin(\phi - \phi_S) \} \tag{A-14} \]

\[ n^{(4)}(\phi) = A_p \gamma_N^N (\alpha_L^P + \alpha_L^B H_{LSN} + \alpha_L^B H_{LLN} + \alpha_S^B H_{SLS} \sin(\phi - \phi_N) + \gamma_L^L (\alpha_L^L L_{LLL} + \alpha_L^B H_{LSL} + \alpha_L^L H_{LNL} + \alpha_S^L H_{SSL} \sin(\phi - \phi_L) + \gamma_S^S (\alpha_L^S L_{LSL} + \alpha_S^S H_{SLS} + \alpha_L^S H_{LNS} + \alpha_S^S H_{SNS} \sin(\phi - \phi_S) \} . \]

The first combination, \( n^{(1)} \), has already been used in the evaluation of the distortion function \( n(\phi) \). The other three combinations can be fitted with

\[ n(j)(\phi) = A(j) \sin\phi - B(j) \cos\phi \]

\[ = C(j) \sin(\phi - \phi_0(j)) \] \tag{A-15} \]

In principle, the spin parameters of interest may now be obtained from the fitted values of the \( A(j) \) and \( B(j) \). However, with limited data this procedure is impractical if the expressions for \( n(j) \) in Eq. (A-13) contain more than two parameters significantly different from zero. In the present experiment, beam and target polarizations were usually aligned so that only
one $a$ and one $b$ were significantly different from zero (see Tables 2 and 3); the $\gamma$ and $\phi$ parameters depend on the momentum of the recoil proton as shown in Fig. 6. Coefficients of spin parameters which contribute to the azimuthal distributions are listed in Table 4. In each case there are only two large terms which contribute to the expressions for $n^{(j)}(\phi)$ in Eq. (A-14).

With this simplification, the equation

$$A \sin \phi - B \cos \phi = C_1 \sin(\phi - \phi_1) + C_2 \sin(\phi - \phi_2) \quad (A-16)$$

gives the spin parameters of interest; here $\phi_1$ and $\phi_2$ are the projected angles in the $X'-Y'$ plane for the respective spin directions. Then

$$C_1 = \frac{A \sin \phi_2 - B \cos \phi_2}{\sin(\phi_2 - \phi_1)},$$

$$C_2 = \frac{-A \sin \phi_1 + B \cos \phi_1}{\sin(\phi_2 - \phi_1)},$$

$$\Delta C_1 = \sqrt{\frac{(\sin \phi_2 \cdot \Delta A)^2 + (\cos \phi_2 \cdot \Delta B)^2}{\sin(\phi_2 - \phi_1)}}, \quad (A-17)$$

$$\Delta C_2 = \sqrt{\frac{(\sin \phi_1 \cdot \Delta A)^2 + (\cos \phi_1 \cdot \Delta B)^2}{\sin(\phi_2 - \phi_1)}}.$$

The final result is obtained by dividing these expressions by the analyzing power and the appropriate coefficient listed in Table 4.
